THUNDERSTORM RELATIVE FREQUENCY DISTRIBUTIONS
FOR USE IN DERIVING THUNDERSTORM FORECAST EQUATIONS

Donald S. Foster

1. Introduction

The screening regression equation for general thunderstorm prediction developed by Reap and Foster (1975) for the 1975 spring and summer months had, as its second term, the six-month averaged relative frequencies of thunderstorms based on a manually-digitized radar (MDR) code of 4 or greater (see figure 1). This term made a very significant contribution to the resultant forecast probability especially in the southeastern states where thunderstorm frequency was high. In fact, it became apparent during the thunderstorm season that the large monthly departures of the relative frequency from the six-month average caused the forecast probabilities to be too high in the early spring and late summer and much too low in mid-summer.

2. Relative Frequencies to be Used in 1976

In an effort to overcome this deficiency before the 1976 season, monthly relative frequencies were computed starting in November 1973. As two years of monthly frequencies became available they were averaged. Figure 2 shows the monthly frequencies compared with the six-month average for one MDR block in southern Alabama. The peak frequency of 60 percent in August is 22% higher than the six-month average. Considering the coefficient of 0.8972 in the regression equation this would result in a probability forecast 20% too low, other factors being the same. In fact, the variation in the monthly frequencies was so large that we decided to offer daily frequencies interpolated from the monthly values as a predictor in deriving the regression equation for 1976. The monthly values will be applied at the middle of the month and a linear interpolation applied on a day-to-day basis between mid-months. We hope this will result in a significant improvement in next year's thunderstorm probability forecasts.

The figures in Appendix A are relative frequency maps for the 2-year period from November 1973 through October 1975. They consist of monthly frequencies for each year and a two-year average. November and December are averaged for 1973 and 1974 while the other months are averaged for 1974 and 1975. A 9-block smoothing routine was applied to each month's frequencies in order to smooth over irregularities. Some blocks were so distant from a radar site that the MDR code may have been reported less than 4 although it would have been more than 4 had the block been closer to the radar site. Even with this amount of smoothing and averaging there are two noticeable areas of suspiciously low frequencies, namely, the areas around northeastern Texas and West Virginia. In spite of this deficiency, the addition of the frequency term is expected to add significant accuracy to the new 1976 thunderstorm probability equation.

The National Severe Storm Forecast Center at Kansas City has asked TDL to expand the thunderstorm probability outlook to a 24-hour period, ± 12 hours from 00Z. In preparation for deriving a forecast probability equation for this period, 24-hour frequencies have been computed from the same 2-year period as the 6-hour frequencies. These 24-hour frequencies are shown in Appendix B.
